Fundamentals and Machine Model

Machine/Memory Model and the Function Call Stack

Object: a piece of data that's stored at a particular location in memory during runtime.

- Variable: a name in source code that is associated with an object at compile time.
- Not all objects are associated with variables; e.g. dynamically-stored objects and string literals are not.
- The value stored by a variable's memory object may change, but the association between a variable and an object itself can only change when the variable goes out of scope.

Static objects "live" for essentially a program's runtime. Local objects' lifetimes are tied to scope (e.g. a block of code or pair of curly braces). Dynamic objects are manually created/destroyed.

(1) Objects declared in a loop body (between the {}) are created/destroyed each time the loop repeats.

Atomic (primitive) types: types whose objects can't be subdivided into smaller objects; includes int, double, bool, float, char, and all pointer types. Atomic objects are default-initialized to undefined values.

```
1 // Four different ways to initialize an int to 5
2 int a = 5; int b(5); int c{5}; int d = {5};
                                                                                                     1 // Explicitly cast an int 'd' to a
2 double e = static_cast<double>(d);
```

The memory allocated to store a function's parameters and local variables during runtime is called a stack frame or activation record. The memory frame for the most-recently called function is added to the "top" of the function call stack and is destroyed when the function returns ("Last In First Out" ordering).

Procedural Abstraction and Program Design

Procedural Abstraction involves using functions to break down a complex procedure into sub-tasks and separate the interface of a procedure (what it does) from implementation (how it works).

Interface examples: declarations in .h files, valid/invalid inputs, RME statements, signature (function name and parameter types), return type, and ADT representation invariants.

Implementation examples: definitions in .cpp files and code/comments inside function bodies.

Pointers, Arrays and References

A pointer is a type of object that stores another object's memory address as its value.

• An int* pointer variable can only point to an int; an int** pointer variable can only point to an int*; and so on. (E.g. attempting to make an int* pointer point to a double will lead to a compile error.)

Dereferencing a pointer: getting the object at an address. Note that the star * operator is used both to declare pointers and to dereference them (and the & operator is used both to get an object's address and to declare a reference).

```
int x = 3; int y = 4;
int *ptr = &x; // ptr initialized to x's address
cout << *ptr; // dereferences ptr/prints 3
ptr = &y; // no star...assigns y's address to pt
*ptr = 6; // dereferences ptr/assigns 6 to y</pre>
```

0x271c 0x2710 z,b 0x2714 0x2710 y

5

0x2710 🛰

Number Swap Function

1 void swap_pointed(int *x, int *y) {
2 int tmp = *x;

*x = *y; *y = tmp;

5 }

```
1 Assigning ptr = ptr2 copies the address stored
    by ptr2 to ptr (subse-
   quently changing ptr2
    wouldn't change ptr).
1 A reference to a reference
```

```
1 int x = 5;

2 int* y = &x; // creates pointer to x

3 int* z = y; // creates another pointer to x

4 int &a = x; // creates reference to z

5 int* &b = z; // creates reference to z

6 cout < *b < end!; // prints 5

7 cout < &y < end!; // prints 0x2714

8 cout < y << end!; // prints 0x2710

9 cout <& &(*z) << end!; // equiv. to cout << &x

10 cout << *(&z) << end!; // equiv. to cout << z
```

is really another reference for the "original" object.

Null pointer: a pointer that holds address 0x0 (which no object can be located at) and implicitly converts to false. Any pointer can nulled; to do so, set it equal to nullptr (0 or NULL also work but are bad style).

Common Pointer Bugs/Errors

▲ Dereferencing a default-initialized pointer results in undefined behavior, as (like all atomic objects) pointers that aren't explicitly initialized are default-initialized to an undefined value (not nullptr).

A Dereferencing a null pointer also leads to undefined behavior (almost always a program crash).

▲ If a function returns a pointer or reference to one of its local variables (which die when the function returns), dereferencing that pointer or using that reference produces undefined behavior. Functions should only return pointers or references to objects whose lifetimes extend beyond the function call.

```
1 int& returnByRef(int x) // BUG
2 { return x; }
1 int* returnPtr(int x) // BUG
2 { return &x; }
                                                                                                                   1 int returnRef(int x) // BUG
2 { int& y = x; return y; }
```

Pointers vs References

References and pointers both enable working between stack

- frames (scopes) and indirection. Some ways they're different: References must be explicitly initialized (unlike pointers). This is because references are aliases for existing objects.
- Pointers must be dereferenced to access the objects they point at, while references are used "as-is".
- You can change the object that a (non-const) pointer points to, while a reference's binding to an object can't be changed.

6 7 int main() { 8 int a = 1216, b = 1261; 9 swap_pointed(&a, &b); Arrays and Pointer Arithmetic

Arrays: fixed-size containers that store objects of the same type (and same size) in contiguous memory.

```
1 // Valid array declarations
2 int arr[3] = {1,2}; // {1,2,0}
3 int zeroArr[3] = {}; // {0,0,0}
3 int mat[][2] = {1,2,3,4};
                                                                                                                                                               1 // INVALID array declarations
2 int junk[4]; // Undefined items
3 int err[2][] = {5,6,7,8}; // No
```

Array decay: using an array in a context where a value is required causes the compiler to convert the array into a pointer to its first element. Array decay is why it's necessary to pass an array's size separately from the array to a function (or to indicate the end of an array with a sentinel character like C-strings do).

▲ Dereferencing a pointer that goes past the bounds of an array results in undefined behavior. But merely using a pointer that goes just past the end of an array without dereferencing it is well-defined.

```
1 void add_five(int arr[], int size) {
2 for (int i = 0; i < size; i++) { arr[i] += 5; }
3 } // arr[i] += 5 is equiv. to *(arr + i) += 5
 int main() {
   int arr[] = { 10, 20, 30 };
   add_five(arr, (sizeof(arr) / sizeof(*arr)));
   add_five(arr, endl; // prints 25
   } // 1[arr] is equiv. to arr[1], but bad style
```

Passing arr by value passes a pointer to arr[0] by value. Also, arr[i] is shorthand for pointer arithmetic followed by a dereference, i.e., arr[i] = *(arr + i).

1 The size of operator returns the size of an object in bytes. In this example, sizeof(arr) alone would return 12, not 3.

```
0 cout << &arr[0],</pre>
   cout << arr, and
   cout << &arr
   would all print
   0×1008
```

```
1 int foo = 7;
2 int& bar = foo; // value of bar is foo (7)
3 int* ptr = &foo;
4 int arr[3] = { 4, 5, 9 };
5 cout << arr << endl; // prints 0x1008 (decay)
6 cout << (arr + 2) << endl; // prints 0x1010
7 cout << (&foo + 1) << endl; // prints 0x1004</pre>
```

	0x1000	7	foo, bar
(0x1004	0×1000	ptr
	0x1008	4	arr[0]
₹	0x100c	5	arr[1]
ļ	0x1010	9	arr[2]

Pointer arithmetic: adding an integer n to a pointer yields a pointer that is n objects forward in memory.

Pointer subtraction: Subtracting two pointers of the same type yields an integer (possibly a negative one) equal to the number of objects between them.

Pointer comparison: comparing pointers of the same type compares the addresses they store.

```
// Mainly for pointers into the same array double arr[u] = {2.5, 5.0, 8.0, 7.0 }; double* ptrl = Sarr[e], *ptrl = Sarr[s]; cout << *arr << endl; // prints 2.5 cout << (ptrl - ptrl) << endl; // prints 3 cout << (ptrl - ptrl) << endl; // prints 3 (ptrl - ptrl) << endl; // prints 3 (ptrl - ptrl) << endl; // prints 3 (ptrl - ptrl); // equates to false (0) ptrl += 2; // ptrl now points at arr[2]
```

```
Using the & operator on an array produces a
pointer to the entire array, not a pointer to the
first element or a pointer to a pointer (& does
not require a value, so it doesn't cause decay).
```

int arr[4] = { 1, 2, 3, 4 };
int (*arr_ptr)[4] = &arr; // pointer to entire array
cout << (*arr_ptr)[2] << endt; // prints 3
// ++arr_ptr would increment by the size of 4 ints</pre>

Traversal By Pointer: arrays can be traversed by pointer (mostly used with C-strings and iterators).

```
Traversal by Pointer: Pattern 2 (C-String Sanitization)
         Traversal By Pointer: Pattern 1
                                                                                          void sanitize_username(Account *acc, char to_remove) {
   char *ptr_a = acc->username, *ptr_b = acc->username;
   while (*ptr_a && *ptr_b) { // while not '\0'
   if (*ptr_b != to_remove) {
1 int const SIZE = 3;
2 int arr[SIZE] = {-1, 7, 2};
2 int arr[SIZE] = {-1, 7, 2};
3 int *ptr = arr;
4 int *end = arr + SIZE;
5 // int* end is just past the end of
6 while (ptr < end) {
7 cout << *ptr << endl;
8 +*ptr; // "Walk" ptr across arr
9 } // Alternative to while loop below</pre>
                                         past the end of arr
                                                                                                      *ptr_a = *ptr_b;
++ptr_a; // ++ptr_a only when a char gets copied
                                                                                                  ++ptr_b; // ++ptr_b every time the loop executes
                                                                                              *ptr_a = '\0'; // null-terminate string when done
1 for (; ptr < end; ++ptr) { ... }
```

The const type qualifier stops objects from being modified after initialization. Note: const scalars must be explicitly-initialized to compile, and const class-type objects must have their data members initialized.

const pointers: pointers that can modify what they point at but cannot be re-pointed to different objects.

Pointer-to-const: read-only pointers; pointers that can be re-bound but can't modify what they point at.

• A const pointer must be initialized to compile, but a pointer-to-const doesn't need to be.

Reference-to-const: a read-only alias.

const array: an array of const elements. Note that the positioning of const matters for arrays of pointers.

```
Special const Type Syntax
int x = 5;
int * const ptr_a = &x; // const pointer
const int * ptr_b = &x; // pointer-to-const
int const * ptr_c = &x; // pointer-to-const
const int * const ptr_d = &x; // both
int const * const ptr_e = &x; // both
const int &ref_a = x; // reference-to-const
int const &ref_b = x; // reference-to-const
const int arr_a[2] = {1, 2}; // array of consts
int const arr_b[2] = {3, 4}; // array of consts
```

const Conversions and Passing

The compiler treats every pointer-to-const as if they point to a const object and every reference-to-const as if they're aliased to a const object. It won't allow conversions that could bypass existing const protections (so, for example, you can assign a const pointer to a pointer-to-const, but the converse is not true).

```
1 int foo(int* a) { ... }
2 int bar(int b) { ... }
3 int func(const int* c) { ... }
4 const int x = 3;
5 bar(x); func(&x); // both ok
6 foo(&x); // ERROR
                                                                                                                                                                                                                                                                                                                    1 int x = 2, y = 5;
2 const int *x_ptr = &x;
3 int *y_ptr = &x;
4 *y_ptr = *x_ptr; // 0k
5 y_ptr = x_ptr; /* ERROR (even 6 though x isn't const) */
                                                                                                                                                                               const int x = 3;
                                                                                                                                                                   1 const int x = 3;

2 int y = x; // 0k

3 const int* cptr = &x; // 0k

4 const int& cref = x; // 0k

5 int* ptr = cptr; // ERROR 1

6 int& ref = cref; // ERROR 2
```

- Pass by pointer/reference: if you need to modify the original object (as opposed to a local copy).
- Pass by value: if an object is small (e.g., an int) and you can't/don't need to modify the original.
- Pass by pointer/reference-to-const: if you want to pass a large object without modifying it.

Strings, Streams and I/O

Creating/Using C-Strings and Strings

Output streams treat pointers to char arrays differently from pointers to other types of arrays

```
1 const char* cstr = "abcd"; // Only works for string literals; use .c_str() on string variables 2 char color[] = "00274C"; // Create 7-element array (including 0) and copy a string literal to it 3 // Note: '0' is the only char that evaluates to false (useful for traversal-by-pointer loops). 4 cout << cstr << " " << *cstr << " " << *cstr << " " << &cstr[] << endl; // prints "abcd a abcd" 5 cout << (cstr + 1) << " << *(cstr + 1) </td>
```

	Length	Copy Value	Index	Concatenate	Compare	
<cstring></cstring>	strlen(cstr);	strcpy(cstr1, cstr2);	cstr[i];	strcat(cstr1, cstr2);	strcmp(cstr1, cstr2);	
<string></string>	str.length();	str1 = str2;	str[i];	str1 += str2;	str1 != str2;	

Pipeline

Streams and File I/O stdin redirection

./main.exe < input.txt ./main.exe > output.txt ./output.	exe input.exe ./main.exe < input.in > output.out					
File I/O Ex 1: Print Lines From File	Ex 2: Copy One File's Contents to Another					
<pre>1 #include <fstream> // defines (if/of)stream objects 2 int main() { 3 ifstream inFS;</fstream></pre>	<pre>1 #include <fstream> 2 int main() { 3 ifstream inFS("input.txt"); // Also valid</fstream></pre>					
4 inFS.open("file.txt"); // valid 5 if (!inFS.is_open()) { return 1; } 6 string_my_string; // initialized to empty string	<pre>4 ofstream outFS("output.txt"); 5 string my_string; 6 while (inFS >> my_string) {</pre>					
<pre>7 while (getline(inFS, my_string)) { 8 cout < my_string << endl; 9 } // could close inFS manually via inFS.close(); 10 } // inFS also closes when scope ends/main returns</pre>	7 outFS << my_string << '\n'; 8 // newline and space both "delimit" strings 9 } 10 }					

istringstream: an object that "simulates" input with a string as its source. Note: an istringstream an ifstream and cin can all be passed to a function with a std::istream& parameter.

stdout redirection

ostringstream: an object that that captures output and stores it in a string. Note: an ostringstream, an ofstream and cout can all be passed to a function with a std::ostream& parameter.

```
#include <sstream> // defines stringstreams
void printPlusOne(istream& is, ostream& os) {
   int num = 0;
while (is >> num) { os << (++num) << " "; }
} // Note: can't pass or return streams by value
istringstream inSS("1 3 5");
ostringstream outSS;
printPlusOne(inSS, outSS);
cout << outSS.str() << endl; // Prints "2 4 6"
```

Command-Line Arguments

 ${\tt argc}$: an int parameter of main representing the number of a command's arguments.

argv: an array of the arguments passed to a program. (Technically, argv is an array of pointers that each point to the start of a C-string—so argv is passed to main as a pointer to an array of pointers to C-strings).

```
#include <string> // defines stoi()/stod()
int main(int argc, char* argv[]) { // char** argv also OK
if (string(argv[1]) == "add") {
int sum = 0;
for (int i = 2; i < argc; i++) {sum += stoi(argv[i]);}
cout < "Sum: " << sum < ", argc: " << argc

< ", argv[i]: " << argv[i] << endt;
} // pay attention to where the "actual" arguments start
} // Also remember to use stoi()/string() when needed
```

ubuntu:~\$./main.exe add 7 2 Sum: 9, argc: 4, argv[1]: add hugokim@ubuntu:~\$./main.exe add 1 2 3 Sum: 6, argc: 5, argv[1]: add hugokim@ubuntu:~\$

Combined redirection

ADTs, Structs and Classes

A struct is a class-type object composed of member subobjects (heterogeneous data). They're passed by value by default, and they support assignment and initialization via the = operator. A struct or class object can also be declared as const, which prevents it and all of its data members from being modified.

- You can't call non-const member functions on a const instance of a class or struct. Also, you can't call non-const member functions from within a const member function.
- Arrow -> operator: shorthand for pointer dereferencing followed by member access. (*ptr).x == ptr->x; 1 Without parentheses, the dot and arrow operators have greater precedence than dereferencing.

Abstract Data Type: a data type that separates its behavior and implementation. ADTs encompass both data and behaviors/functions that act upon it. Not all structs are ADTs, some are "plain old data".

Avoid accessing the member data of an ADT directly (even in tests) because it breaks the interface.

C++ Classes

In C++, the only real difference between classes and structs are that classes have private member access and private inheritance by default while structs default to public access/inheritance.

Constructors

- 1 The compiler implicitly creates a default ctor iff there are no user-defined ctors.
- 1 The order in which members are declared in a class is always the order they're initialized in.
- Initialization values from a member init. list overwrite initializations made during declarations.
- A Data members that aren't included in a ctor's member initializer list or initialized at declaration get default-initialized/constructed.
- A delegating ctor must contain a call to the other ctor (and nothing else) in its member init. list.

```
Constructor Definition Example
class Animal {
private: string name;
public:
class Duck : public Bird {
```

```
C-Style Struct vs Class Syntax
```

```
ADT Function Definition
// C-Style Struct
// C-Style Struct
void Triangle_scale(Triangle *t, double s) {
   t->a *= s; // "->" is necessary here
} // struct pointer is explicitly passed
// C++ Class (Inside Body)
class Triangle { // "this->" is optional here
void scale(double s) { this->a *= s; }
}; // this-> implicit iff no name conflicts
// C++ Class (Outside Body)
void Triangle::scale(double s) { ... }
```

```
Object Creation/Manipulation
   // C-Style Struct
  // C-Style Scheck
Triangle t1;
Triangle_init(&t1, 3, 4, 5);
// C++ Class
Triangle t1; // Calls default ctor
Triangle t2(3,4,5); // calls 3-argument ctor
Triangle t3 = Triangle(3,4,5); // ditto
// Syntax that works for classes AND structs:
Triangle t4{3, 4, 5};
Triangle t5 = {3, 4, 5};
Triangle t6 = Triangle{3, 4, 5};
```

```
const function definition
// C-Style Struct
double area(const Triangle *t) { ... }
// const goes inside argument list
// C++ Class (Inside Body)
class Triangle {
  double area() const { ... }
}; // const comes after signature
// C++ Class (Outside Body)
double Triangle::area() const { ... }
```

Nested Classes and Constructors

To initialize a nested class object, initialize it with a valid argument for the nested class's ctor.

Nested class objects in a const class object are also const.

```
class Book {
public:
                                                                          class Person {
                                                                    public:
    Person(string& n, double p)
    : name(n), favBook(p) { }
private:
    public:
   Book(double price_in)
   : price(price_in) { }
// Note: no default Book ctor
                                                                             string name;
Book favBook;
6 private:
7 double price;
8 }:
```

Inheritance and Polymorphism

Function Overloading (Ad Hoc Polymorphism) and Operator Overloading

Function Overloading: using one name to refer to functions with different signatures. Functions can only be overloaded in the same scope (otherwise the "closer" scope takes priority). Note: const/non-const passing only alters the signature of functions with pointer/reference parameters (or implicit this-> pointers). Operator Overloading: operators like +, -, <<, etc. must be "overloaded" either as a top-level or class member function to work properly with custom classes (at least 1 operand must be of class-type).

• An operator must be overloaded as a top level function if the first operand is an atomic type or a class type whose definition we can't access (e.g. ostream). Also, the =, (), [] and -> operators can only be overloaded as member functions (along with overloads that need to access private members).

```
[] overload example (member)
1 class IntSet {
      // contains() is also a member function
    bool operator[](int v) const;
bool IntSet::operator[](int v) const {
   return contains(v);
```

```
<< and == overload example (top-level)
1 class Line {...}; // start/end are public members
sostream& operator<<(ostream& os, Line line) {
return os << line.start << line.end;
} // os needs to be passed by non-const ref here</pre>
 bool operator==(const Line &a, const Line &b) {
  return (a.start == b.start && a.end == b.end);
} // Don't pass by non-const ref here
```

Inheritance and Derived Classes

All base class members (EXCEPT ctors and dtors) become implicit members of derived classes. So you can call any non-private base class function on a derived class object or access non-private inherited data members via (.)/->

▲ Creating a derived class object always calls a base class ctor. If you don't call one explicitly, the compiler will implicitly try to call the base default ctor (causing a compile error if it doesn't exist/isn't accessible). Also, a base class dtor is always called when a derived object dies.

Member name lookup via (.)/-> starts in the "first" class scope; if no match is found, the base class scope (if one exists) is searched. Lookup stops at the first match; member access levels are checked after name lookup finishes.

```
class Base {
     void print() { cout << "B" << endl; }</pre>
class Derived : public Base {
void print_b() { Base::Print()
void print() { cout << "D" << endl; }
void print_b() { Base::print(); }</pre>
3;
Derived d;
d.print(); // prints "D"
d.print_b(); // prints "B"
d.Base::print(); // prints "B"
Base* b = &d; // another way to un-hide
b->print(); // prints "B"
```

Attempting to overload functions inherited from a base class will "hide" them, not overload them.

```
Indirect access of inherited privates
 1 class Base {
2 private:
3    int x = 5;
4 public:
5   int* x_ptr = &x;
6    int get_x() const { return x; };
  7 };
3 class Derived : public Base { };
```

1 2 3	Derived	d; // cannot directly access x
2		*(d.x_ptr) << endl; // prints 5
3	cout <<	d.get_x() << endl; // prints 5

Summary: how access modifiers affect direct access							
Modifier	Accessible to derived classes	Accessible out of scope					
public	✓ Yes	✓ Yes					
private	× No	× No					
protected	✓ Yes	× No					

Destructors: special functions that are invoked when a class object's lifetime ends (e.g. when you delete a dynamic object or when a local object goes out of scope). Syntax: Triangle::~Triangle() {}

for derived class objects, constructors follow top-down behavior (i.e., the base class ctor is called first), while destructors are bottom-up (the derived class dtor is called first, and the base dtor is called last).

Subtype Polymorphism and Class Casting

Subtype polymorphism allows a publicly-derived class object to be used in place of a base class object; to do this, a base class reference or pointer to a derived class object must be created.

```
class Bird { }; // Base class class Chicken : public Bird { }; class Duck : public Bird { }; bird b; Chicken c; Duck d; b = c; // Legal, but "slices" c's data Bird* b.ptr = &c; // Good, no slicing c = b; // ERROR (illegal assignment) Chicken* c.ptr = &b; // ERROR (downcast) Duck* d_ptr = &c; // ERROR
```

C++ allows implicit upcasts (i.e. base pointers/refs to publicly derived objects), but all downcasts must be explicit via static_cast or (less preferably) dynamic_cast.

1 // Be careful - validity not checked at runtime:
2 Chicken *cPtr_a = static_cast<Chicken *cPtr_ptr);
3 // Bird needs at least 1 virtual function for this:
4 Chicken *cPtr_b = dynamic_cast<Chicken *>(bird_ptr);

6 An invalid dynamic_cast evaluates to nullptr, and an invalid static_cast will cause a runtime error.

Virtual Functions and the override Keyword Here, the receiver of the call to talk() on line 13 has a static type known at compile time (Bird) and a dynamic type known at runtime

(Duck). Member lookup starts in the static class, so Duck::talk won't hide Bird::talk, Instead. Bird::talk is declared as virtual to make it dvnamically-bound.

Declare a function as virtual when a receiver's static and dynamic type are different and you want to use the dynamic version of the function.

```
1 class Bird {
2 ... // virtual can only be used in a class body
3 virtual void talk() const { cout << "tweet"; }</pre>
    4 };
5 // Note: ctors can't be virtual, but dtors can
6 class Duck: public Bird {
7 ... // "virtual" is optional/implicit here
8 void talk() const override { cout << "Quack"; }
9 }; // override = an optional 'sanity check"
1 Duck duck;
2 Bird* duck,ptr = &duck;
3 duck_ptr-talk(); // prints "Quack"
4 // Scope resolution operator can suppress virtual
4 // Scope resolution operator can suppress virtual
13 duck_ptr->talk(); // prints "Quack"
14 // Scope resolution operator can suppress virtual
15 duck_ptr->Bird::talk(); // prints "tweet"
```

override keyword: tells the compiler to verify that the function overrides a base-class virtual function with a matching signature (if no override is found, override causes a compile error).

Pure Virtual Functions and Abstract Classes

Pure virtual function: a virtual base-class function that has no meaning or implementation; they simply make up part of the interface for derived classes. To declare one. add = 0: to the end of a function's signature.

Abstract class: a class with at least one pure virtual member function. Note that derived classes of an abstract class will also be abstract unless they override (define) every pure virtual function they inherit.

Interface (pure abstract class): a class that contains nothing but pure virtual member functions.

 $Useful \verb|<| vector>| functions|$

```
class Abst { // Abstract Class
public: virtual void foo() = 0;
}; // Note the lack of empty braces
class Concrete : public Abst {
public: void foo() { cout << "foo"; }
}; // public/private doesn't matter here</pre>
Concrete c;
Abst* c_ptr = &c; Abst& c_ref = c; // ok
Abst abst_object; // COMPILE ERROR
c.Abst::foo(); // RUNTIME ERROR (or U.B)
```

1 Don't call pure virtual functions or try to instantiate abstract classes.

Container ADTs and Templates (Array-Based Data Structures)

Container ADTs

static keyword: used to make one copy of a class data member "shared" between all instances of that class. A static data member has static storage duration but exists only within the scope of a class.

Vectors: resizable array-based container ADTs that store elements at the front and free space at the back

```
stack: a container that's designed to
                                                               Stack and Queue Interfaces
operate in a LIFO order.
                                                             Operations - optimal implementations are all O(1)
                                            Container
                                             Stack
                                                                   back/top (next)
                                                      empty size
queue: a container designed to operate
                                                                                        push_back pop_back
                                           Queue empty size front (next) back (last) push_back pop_front
in a first-in/first-out (FIFO) order.
```

1 An efficient way to implement a queue is to create a vector with free space at both ends (a ring/circular buffer). To do so, keep track of the data using head (inclusive) and tail (exclusive) variables. Operation Unsorted Set Sorted Set Stack Queue

	.size() v[i] .push back(val) .pop back() .resize(n)				insert, remove	O(n)	O(n)	O(1)*	O(1)*	O(n)	
.S1Z0	e()	v[i]	.push_back(val)	.pop_back()	.resize(n)	contains	O(n)	$O(\log n)$	O(n)	O(n)	O(n)
.fron	t()	.back()	.at(i)	.empty()	.clear()	access	O(1)	O(1)	O(n)	O(n)	O(1)
	SortedIntSet::remove() implementation					SortedIntSet::insert() implementation					
2 3	<pre>1 void remove(int v) { 2 int i = indexOf(v); // indexOf() is a member 3 if (i == 1) { return; } 4 for (; i < elts_size - 1; ++i) { 5 elts[i] = elts[i + 1];</pre>					<pre>3 int i = e 4 for (; (i</pre>	of(v) != -1	lts[(i-1)]	, . > v)	; i)	

Templates (Parametric Polymorphism)

--elts_size; // elts_size == cardinality

Templates: flexible models for producing code that take a data type as a parameter to create an object or call a function that works with that type. They help reduce code duplication in container ADT interfaces.

```
Function Template Syntax
                Class Template Syntax
                                                                                                template <typename T> // "T" = an arbitrary parameter name
// Note: "class" also works in place of "typename".
T maxValue(const T &valA, const T &valB) {
    return valB > valA ? valB : valA; // Note: "?" = ternary
} // This function returns the greater of valA and valB
// Syntax to call it: maxValue<int/double/etc>(...);
   template <typename T>
class UnsortedSet {
public:
    void insert(T my_val);
    bool contains(T my_val) const;
    int size() const;
   private:
   T elts[ELTS_CAPACITY];
                                                                                                                  Templated Class Member Function Syntax
        int elts size:
                                                                                           1 template <typename T> // Necessary if outside class body
2 void UnsortedSet<T>::insert(T my_val) {...}
11 }; // Syntax: UnsortedSet<type> s;
```

A template can accept an invalid type argument during instantiation (leading to a runtime error).

Iterators, Traversal By Iterator, and Range-Based Loops

Iterators: objects that have the same interface as pointers; they provide a general interface for traversing different types of container ADTs. To implement an iterator for a particular ADT, define them as a nested class within the container's class and overload the \star (dereference), ++, ==, != operators.

1 std::begin() returns an iterator to the start of an STL container. std::end() returns an iterator that's 1 past the end of an STL container (the iterator returned by std::end() should not be dereferenced).

Traversal By Iterator: a more general form of traversing a container data type by pointer.

```
1 vector<int> v(3, -1); // this syntax initializes v to {-1,-1,-1}
2 for (vector<int>::iterator it = v.begin(); it != v.end(); ++it)
3 { cout << *it << endl; } // ::const_iterator if const vector</pre>
```

```
Range-Based For Loop (Works on Any Sequence Traversible by Iterator)
1 vector<int> v = { 1, 2, 3, 4 };
2 // for (<type> <variable> : <sequence>) {...}
3 for (int item : v) { // works with arrays too cut cut ex cend;
5 } // could also declare item as const or a ref
                                                                                                                             1 // Compiler translation of range-based for loop
2 for (auto it = v.begin(); it != v.end(); ++it) {
3    int item = *it;
4    cout << item << endl;</pre>
```

Time Complexity

We define runtime complexity in terms of number of steps, not literal runtime. Big-O notation represents an upper-bound of the magnitude of a function's growth rate with respect to input size (thus, all O(n)functions are also $O(n^2)$, $O(n^3)$, etc). Big- Θ and Big- Ω represent average and lower bounds, respectively.

§ Functions in the same complexity class should have growth rates that differ by a constant factor as $n \to \infty$. So $O(2^n)$ and $O(8^n)$ are NOT in the same complexity class, but $O(\log_2 n)$ and $O(\log_3 n)$ are.

Determining Asymptotic/Big-O Complexity

Constant coefficients: if they're not part of an exponent, ignore them. Ex: O(3n) = O(0.5n) = O(n).

Addition (sequential procedures): the highest-complexity term dominates. Ex: $O(n^2 + n + \log n) = O(n^2)$.

Multiplication: multiply the individual terms' complexities. Ex: $O(n \times \log n) = O(n \log n)$.

Non-nested loops: sum the complexities of each operation inside the loop body, and then multiply that by the number of times the loop executes. Ex: a loop that runs from 0 to n with a $O(\log n)$ body is $O(n \log n)$. Nested loops: start at the innermost loop and work outwards (the individual complexities of the loops

should multiply). Ex: two nested O(n) loops will do n work n times, so they're $O(n^2)$. Partitioning/repeated division: procedures that divide the "remaining steps" by a constant number each time they execute (e.g. binary search, for-loops that double the loop counter) are usually $O(\log n)$.

```
\log(xy) = \log(x) + \log(y) \quad \log\left(\frac{x}{y}\right) = \log(x) - \log(y) \quad \log(x^n) = n\log(x) \quad \log_b(x) = \frac{\log_c(x)}{\log_c(b)} = \frac{1}{\log_c(b)}
```
